CSAE Working Paper WPS/2018-05

Fading Choice: Transport Costs and Variety in Consumer Goods*

Jan Willem Gunning†, Pramila Krishnan‡ and Andualem T. Mengistu§

April 23, 2018

Abstract

The lack of market development in remote areas is usually measured by spatial variation in prices for a given set of consumer goods. We focus instead on the way distance constrains the choices consumers can make. We construct a model of monopolistic competition between traders moving goods from market towns to rural areas. An increase in transport costs reduces consumer welfare not only through lower incomes for farm households and higher prices for manufactures but also through reduced availability of manufactures: choice fades with distance. The model allows for heterogeneity of villages in terms of market size and the distribution of income. We test the model using data from a purpose-designed survey of shops and consumers in rural villages in Ethiopia. Falling transport costs, larger market size and higher inequality dramatically raise variety of items and brands available locally. We use data on prices of matched source and destination goods to estimate similar tastes for variety across space and estimate an average markup of 10-15 percent. We use these results to estimate the welfare costs of falling variety at between 5-7 percent of expenditures on manufactured consumer goods. Our results suggest ignoring the costs of lower variety in remote places will mean that the level of poverty is underestimated while the rate at which poverty declines is underestimated as well.

1 Introduction

Transport costs reduce consumer welfare not only through lower incomes and higher prices but also through reduced variety: choice fades with distance. Studies of market development typically focus on the spatial integration of markets as measured by price wedges for goods traded across space (see Fackler and Goodwin (2001) for a review). In contrast, the literature on spatial variation in product variety is sparse. Our focus is on the choice of varieties in domestic markets in contrast to most studies of the extensive margin that focus on across countries. We use data from a purpose-designed survey of shops and consumers in rural villages in Ethiopia to understand how remoteness reduces the variety of consumer goods available and the costs to consumers of fading choice.

Why might remoteness affect product variety? First, in remote areas, previous research (Jacoby and Minten (2009), Jacoby (2000), Minten and Kyle (1999), Minten et al.(2013), Stifel and Minten (2008), Dercon et al. (2009) and Khandker et al. (2009)) has shown that productivity is low and poverty is more intense. In the case of Ethiopia for instance, the costs imposed on farm households due to remoteness alone lower incentives to use potentially profitable inputs: Minten et al.(2013) show that incentives for fertiliser use decline quickly over space because output to input price ratios drop by half. Dercon et al. (2009) report that access to all-weather roads increases consumption growth by 16 percentage points and, reduces the incidence of poverty by 7 percentage points. Thus, if the demand for variety has a positive income elasticity\(^1\), then remoteness will be also be associated with a reduction in variety. Second, high transport costs imply that individual varieties will be more costly in rural areas. With any fixed cost of varietal marketing, this will give rise to a reduction in the set of varieties. And third, the pricing power of retailers in remote areas, where market size may be too small to support much competition, may imply that shopkeepers prefer to restrict the set of varieties in order to focus on products with high margins. We investigate the effects of transport costs, incomes and market size on the variety of products available across space in what follows below but before we do so we turn to a brief summary of the related literature.

While the literature on product variety within countries is thin, the effects of fixed costs and scale, incomes and market size have been extensively examined in trade across countries. The theoretical literature on the effect of scale economies in international trade (e.g. Krugman 1980; Helpman 1984) provides a framework for understanding how transport costs reduce the variety of goods available.

---

\(^1\)Li (2011) examines the Engel curve for variety in India, with positive estimates of the elasticity of variety in food consumption.
has inspired a large empirical literature on the extensive margin or variety in trade. Hummels and Klenow (2005), for example, find that larger and wealthier countries trade more, and that 60 percent of the difference in aggregate trade flows comes from differences in the number of goods traded. Smaller countries will have less variety in consumption as a result of fixed costs, both in production and in international trade. This literature suggests that there is a strong response of the extensive margin to changes in trade barriers or country size (Broda and Weinstein (2006), Eaton et al. (2011), Chaney (2008)). Relatively little is known, however, about the variety in domestic trade. For the U.S.A., Handbury and Weinstein (2014) examine detailed barcode data on purchase transactions by households in 49 U.S. cities and find that biases in spatial price measurement due to heterogeneity in quality and the availability of variety are large: correcting for these, they find food prices lower in bigger cities. Handbury (2012) finds systematic variation in the living costs faced by consumers in different income classes and demonstrates that these differences are driven by cross-city variation in product variety rather than prices. Conventional price indices compare only the prices of goods common to locations and ignore differences in variety across locations thus fail to account for such differences in living costs.

Indeed, as far as we are aware, this is one of the few papers to document the spatial variation in variety and to examine the role of local demand and transport costs in explaining it. We assess the welfare effects of transport costs through the channel of reduced variety, allowing for heterogeneity across households in income. We model the number of varieties available by location to understand the local retail environment and use data on local availability of varieties to understand the variation in varieties across villages. Li (2011) offers an excellent complement to the discussion in this paper: using data on variety in food consumption across India, he documents an Engel curve for variety. In contrast to our approach, he takes the local retail environment as exogenous. He discovers substantial welfare effects in food consumption over time with welfare gains accruing largely to rich and urban households and points to the association between consumption diversity, economic development and urbanisation. Two other fascinating and complementary pieces examine the role of reducing trade and transport costs via the expansion of e-commerce in China. Fan et al. (2016) documents the fall in domestic trade costs through the rise of e-commerce in China: using data from the e-retailer Alibaba, they...
examine the implications of falling costs in reducing spatial consumption inequality. Staying in China, Couture et al. (2018) combine an experiment with survey and administrative microdata to provide evidence that e-commerce leads to a significant reduction in cost of living via lower prices and increased product variety.

Differences in prices of goods traded within developing countries have attracted more attention than variety\(^4\). Atkin and Donaldson (2015) use spatial price differences from official price surveys in Nigeria and Ethiopia as a proxy for trade costs within developing countries. Van Leemput (2016) quantifies the size of internal versus external trade barriers in India and finds that reducing internal trade barriers across states within India offers twice the welfare gains compared to reducing international barriers in terms of price integration.

There are two reasons why the literature on the differences in variety across space is sparse. The first is that household and other surveys typically do not obtain information on availability at retail outlets. The second reason is the difficulty in identifying the impact of transport costs. The causal identification of the impact of roads using cross-sectional data is near impossible given that roads are usually constructed for some reason, often with economic returns in mind, that is likely to be conflated with other characteristics that also affect outcomes of interest (Adam et al. (2016)). Plausible studies of the impact of roads have relied on randomised roll-out of road improvements (e.g.Casaburi et al. (2013) Gonzalez-Navarro and Quintana-Domeque, (2016)) or instrumental variables (Banerjee et al. (2012), Storeygard (2016) and Donaldson (2016)). An alternative strategy used by Jacoby and Minten (2009) and Minten et al.(2013) relies on an innovative survey of households in a small, relatively homogeneous regions of rural Madagascar and Ethiopia, over which transport costs to the same market vary tremendously, due not to the placement of roads but to the terrain.

We implement a similar strategy as in Jacoby and Minten (2009) to identify the effect of remoteness on varieties available, using data from a purposive survey of retail outlets and local traders in Ethiopia. There are two key concerns that we seek to address. The first is that road infrastructure is not randomly built across districts and villages; we needed to account for this non-random placement effect. By sampling up to three villages in the same district, and focusing on within district variation, we can account for placement at the level of the district. In addition, we find no real evidence of placement effects within districts on observable factors

\(^4\)For developed countries there are also some estimates, e.g. Handbury and Weinstein (2014) and Handbury (2012) for the US. Handbury (2012) finds that price differences for different income groups are driven entirely by variety differences across cities.
but perhaps more telling is that district fixed effects account for the type of road in over half of\nthe villages surveyed. The second issue is the matching of goods at destination with their origin\nin order to correctly assess the impact of transport costs. First, accounting for the variation\nacross districts allows us to concentrate on the relationship between the local (within district)\nsupply of variety in goods and local transportation costs, local (average) incomes and local\nheterogeneity in incomes. The second concern, the matching of origin and destination in the\nsupply of goods required that we do so by designing the survey so that the local market town\nis the only supplier of consumer goods and can thus serve as a benchmark for local availability.\nThis is explained in detail later in this paper.

We conducted a survey of 296 villages in 100 districts across the four main regions of Ethiopia.\nWe focus on manufactured consumer goods: this covers about 20 item groups from processed\nfoods, drinks, garments, footwear, cosmetics to kitchen ware, hardware and small electronics.\nWithin these groups there are specific items such as pasta, beers, soaps, plastic tableware,\nlinens, notebooks, and batteries and we can further disaggregate many of these by specific\nbrands. Data were collected in shops in the market towns closest to the villages and in shops\nand periodic markets (served by traders) in villages. Village officials and six households in\neach village were surveyed. These data allow us to examine how transport costs, incomes,\nthe income distribution and size of the local market affect the fraction of items available in a\nremote village compared to its nearest market town. We construct a theoretical framework of\nmonopolistic competition among traders in manufactured goods to examine the relationship\nbetween remoteness, incomes and market size; we also use it to calibrate the welfare impacts\nof living in remote areas.

Our main contribution, arising from our results on the availability of variety across space, is\nto show that the loss of variety can lead to a substantial welfare loss for households who live\nfar from market towns. In particular, we complement the discussion on the effect of variety in\ndomestic trade which has focused on the impact on prices across space(Atkin and Donaldson\n(2015) Handbury and Weinstein (2014), Handbury (2012)and Glaeser et al. (2001)) and extend\nthis to the impact of space on variety.

The paper is structured as follows. The next section discusses the theoretical framework in\ntwo parts. We begin with a simple model of trade and transport, with homogeneous agents.\nWe then generalise this to account for heterogeneity in incomes since it is plausible that the\ndistribution of income might have a separate effect on variety supplied locally. We follow this
in Section 3 with a description of the purposive survey and the data obtained and describe the rationale for the design. Section 4 offers results on how choice varies with travel times together with estimates of the price mark-ups across space. Section 5 uses these results to estimate the welfare costs of remoteness. Section 6 concludes.

2 Model of Transport Costs and Availability of Consumer Goods

2.1 The basic model

We begin with a very simple model of trade and transport to investigate how consumers are affected by transport costs, not only through changes in prices, but also through changes in the set of goods they can buy.

We assume Dixit and Stiglitz (1977) preferences:

\[ u = \sum_{i=1}^{n} c_i^\theta \quad 0 < \theta < 1 \] (1)

where \( c_i \) denotes consumption of good \( i \), the consumer takes the number of available goods \( n \) as given, and \( 1 - \theta \) is a measure of the consumer’s taste for variety and \( y \) denotes income. For \( \theta \to 1 \) the consumer treats different goods as close to perfect substitutes, for \( \theta \to 0 \) as complements.

The consumer solves:

\[
\max_{c_1, \ldots, c_n} \sum_{i=1}^{n} c_i^\theta \quad \text{subject to} \quad \sum_{i=1}^{n} p_i c_i = y.
\] (2)

The first-order condition gives:

\[ c_i = \left( \frac{\theta}{\lambda p_i} \right)^{\frac{1}{1-\theta}} = \frac{y}{np_i}. \] (3)

Here \( \lambda \) denotes the Lagrange multiplier of the budget constraint. An immediate implication
of (3) is that the price elasticity of consumer demand decreases with the taste for variety: the more the consumer cares about variety the more inelastic demand and hence the greater the monopoly power of the trader.

We consider transport and trade to $J$ villages ($j = 1, ..., J$), each connected by its own road to a market town where all $n$ goods are available at a given price. The distance between village $j$ and the town is $s_j$. Each village has $m$ consumers whose income is derived from selling a crop. This income is fixed at $y^*$ at $s = 0$ and declines with the distance from the market town, reflecting iceberg transportation costs:

$$y_j = \frac{y^*}{\gamma s_j}. \quad (4)$$

(The assumptions that villages have the same number of consumers and that incomes are equal within a village will be relaxed in the next section.)

Since goods are modelled symmetrically we can drop the index $i$. Each trader deals in a single good which he buys in the market town at a given price $\bar{p}$ and transports to a subset of the villages where the good is sold at the price $p^*_j$. The cost of transporting a quantity $q$ over a distance $s$ is $(\alpha + \beta q)s$. Hence the trader’s profits on sales at $j$ are given by:

$$\pi_j = [p^*_j - (\bar{p} + \beta s_j)](m.c) - \alpha s_j. \quad (5)$$

Traders are engaged in monopolistic competition. Hence each trader sets a profit maximising price taking into account the demand curve (3). From (3) and (4) this gives for locations that are served:

$$p_j^* = \frac{\bar{p} + \beta s_j}{\theta}. \quad (6)$$

This shows that each trader charges a markup over marginal costs $\bar{p} + \beta s_j$ and that this markup is increasing in the taste for variety $1 - \theta$.\(^5\)

\(^5\)Note that for $\theta \to 1$ the markup vanishes: if consumers have no taste for variety then marginal cost pricing is, of course, optimal.

\(^6\)Benassy (1996) points out that this formulation locks the taste for variety to the elasticity of demand and suggests an alternative formulation that would separate the two parameters. While this is theoretically appealing, it is clear that the taste for variety parameter thus separated affects only unobservable variables, namely welfare and the number of optimal varieties (see Section 6 in Benassy (1996)) and hence is unidentifiable in a fundamental sense.
location. From (3)-(5) and the budget constraint this implies:\(^7\)

\[
n_j = \frac{(1 - \theta)my^*}{\alpha \gamma s_j^2}.
\]

Equation (7) indicates that at a distance \(s_j\) from the market town the number of goods available is increasing in the taste for variety and in the size of the market \((my_j)\), measured in terms of fixed transport costs, \(my_j/(\alpha s_j) = my^*/(\alpha \gamma s_j^2)\).

In this model a reduction in transport costs (a lower value of \(\alpha, \beta, \) or \(\gamma\)) increases consumer welfare in three ways. First, from (4), when \(\gamma\) falls the value of income increases. Secondly, from (6), when a fall in \(\beta\) reduces the price of consumer goods so that (for given \(n_j\)) consumption of each of the available goods increases. Finally, a fall in \(\alpha\) increases the number of goods available in a given location. This reduces consumption of each good but raises welfare because of the consumer’s taste for variety. We call these three effects the income effect, the price effect and the variety effect respectively.

One of the key assumptions here is the existence of fixed costs. This is particularly salient in this setting as we discovered upon interviewing traders. These costs include licences (by either items or groups of items), payment to village authorities\(^8\), and the costs of own transport and accommodation for itinerant traders as well as inventory and storage costs. Table 1 offers a summary of why traders specialise in items: 38% of traders quote licences required as the reason for not trading other items, 33% quote lack of capital while 20% claim that the lack of demand in remoter areas dissuades them from carrying more items.

In the Dixit-Stiglitz specification goods are modelled symmetrically so that in equilibrium prices and quantities are the same for all goods consumed. A corollary is that the equilibrium is affected only by market size (total income in a village), not by the way income is distributed. This is a serious limitation. In the next section we therefore drop the symmetry assumption. As a result the number of goods available in a specific location will depend on the distribution of income.

\(^7\)For simplicity we treat \(n\) as a continuous variable.

\(^8\)The existence of fixed lump sum fees per trader is attributed to a combination of land regulation and tax policy. Rozelle et al. (2003) describe similar difficulties facing itinerant traders in rural China: “Local officials clearly understand how difficult it is to collect taxes from itinerant peddlers. As a consequence, officials spend little time trying to collect value-added taxes, relying instead on simple taxation methods such as collecting stall fees or negotiating lump sum fee payments.”
2.2 Market size and Inequality

For the time being we maintain the assumption that consumers are identical in terms of income. However, we change the utility function by grafting onto the Dixit-Stiglitz specification the two key features of the Murphy et al. (1989) specification. First, beyond a certain level, $\bar{c}$, the consumer can raise his utility only by consuming new goods rather than consuming more of the same goods. Secondly, marginal utility declines not only as consumption of the same good increases (as in the Dixit-Stiglitz specification) but also as more goods are consumed. Marginal utility for good $i$ is now given by:

$$u_i = \begin{cases} \frac{\theta v_i}{c_i^{1-\theta}} & \text{if } 0 < c_i \leq \bar{c}, \\ 0 & \text{if } c_i > \bar{c}. \end{cases}$$

(8)

where the parameters $v$ satisfy

$$v_i > v_{i+1} > 0 \quad i = 1, 2, ..$$

If $n$ goods are available in the location utility maximization gives:

$$c_i = \min\left(\frac{\theta v_i}{\lambda p_i}^{\frac{1}{1-\theta}}, \bar{c}\right) \quad i = 1, 2, .., n.$$  

(9)

Prices $p_i$ are equal across goods and equal to a village specific price level $p^*_j$. The trader’s profit maximisation gives (as before):

$$p^*_j = \frac{p + \beta s_j}{\theta}.$$  

Note that the parameters $v$ affect consumption levels but not prices. Since new goods have lower marginal utility, $c_i$ decreases with $i$. If the consumer’s income is sufficiently low $c_1 < \bar{c}$ so that

$$\bar{c} > c_1 > c_2 > .. > c_n$$  

(10)

while at higher income levels consumption of the first $k$ goods ($n > k \geq 1$) will be at the bound:9

9We ignore the extreme case $k = n$. In that case part of the consumer’s income would be useless: spending it would not add to utility. This is an empirical point: in Ethiopia, the ”excess” income is likely to be held in
\[ c_i = \bar{v} \quad i = 1, \ldots, k; \quad \bar{v} > c_{k+1} > \ldots > c_n. \]  

(11)

As income rises \( k \) will successively take the values 1, 2, ...

We now relax the assumption that the consumers at a given location are identical. Instead there now are \( m_{jH} \) rich consumers with income \( y_{jH}^* \) in the village and \( m_{jL} \) poor consumers with income \( y_{jL}^* \).\(^{10}\) We assume that \( y_{jL}^* \) is sufficiently low for (10) to hold and \( y_{jH}^* \) sufficiently high for (11) to hold.\(^{11}\)

The number of goods available, \( n_j \), is determined by the zero profit condition for the last good:

\[
[p_j^* - (\bar{p} + \beta s_j)](m_{jL}c_{njL} + m_{jH}c_{njH}) = \alpha s_j.
\]

or

\[
m_{jL}c_{njL} + m_{jH}c_{njH} = \frac{\alpha s_j}{\bar{p} + \beta s_j} \frac{\theta}{1 - \theta}
\]

or, using the two budget constraints:

\[
m_{jL}^{y_{jL}^*} v_{n_j}^* \frac{v_{n_j}^*}{\gamma s_j v_1^* + \ldots + v_{n_j}^*} + m_{jH}^{y_{jH}^*} (\frac{y_{jH}^*}{\gamma s_j} - p_j^* k\bar{v}) \frac{v_{n_j}^*}{v_{k_j+1}^* + \ldots + v_{n_j}^*} = \frac{\alpha s_j}{1 - \theta}
\]

(12)

where

\[
v_i^* = v_i^{1/(1-\theta)}.
\]

The equilibrium condition in equation (12) determines the number of goods available, \( n_j \). The left hand side (LHS) of this equation measures the value of total consumption for the last good, \( n_j \), in the village.\(^{12}\) Note that the LHS is decreasing in \( n_j \). Hence any change that increases the LHS must be offset by an increase in \( n_j \). It follows that \( n_j \) is increasing in the size of the two groups (\( m_{jL} \) and \( m_{jH} \)) and in their incomes (\( y_{jH}^* \) and \( y_{jL}^* \)). Availability is also increasing in market size, measured by total village income \( m_{jL}y_{jL}^* + m_{jH}y_{jH}^* \). Less obviously,

livestock assets.

\(^{10}\)We assume throughout that \( y_{jL}^* < y_{jH}^* \).

\(^{11}\)If (10) would hold for both groups then the rich would consume more of each good in proportion to their income:

\[ c_{iH} = c_{iL}(y_{iH}^*/y_{iL}^*) \]

and in this case inequality would not matter: the number of goods available would be determined by total market size (as in the Dixit-Stiglitz model), irrespective of the distribution of income.

\(^{12}\)Since \( n_j \) is integer (12) will not hold as an equality. Instead in equilibrium the LHS \( \geq \) RHS (where RHS denotes the right hand side) and LHS \( < \) RHS if \( n_j \) is replaced by \( n_j + 1 \). Hence the last trader may make a profit but there is no incentive for a new trader to enter the market with a new good.
availability increases with income inequality: a mean preserving spread in the distribution of income increases $n_j$. Intuitively this is because the poor spend an increase in income on all goods, the rich only on those goods for which their consumption has not yet reached the level $\bar{x}$. A mean preserving spread will therefore raise total demand for the marginal good and this induces an increase in variety.

More precisely, the effect of a mean preserving spread (an increase in $y^*_j$ offset by a reduction in $y^*_L$ so as to keep total income $m_jL y^*_jL + m_jH y^*_jH$ and hence mean income constant) is given by the partial derivative

$$\frac{\partial LHS}{\partial y^*_jL} = \frac{m_jH}{p_j^*} \left[ \frac{v^*_n}{v^*_{k,j+1} + \ldots + v^*_n} - \frac{v^*_v}{v^*_1 + \ldots + v^*_n} \right] > 0$$

where $n_j$ is kept constant. This increase of the $LHS$ calls for an offsetting increase in $n_j$. Hence an increase in inequality unambiguously improves variety, $n_j$. This is an important testable implication of the model.

It should be noted that in this framework both the rich and the poor consume the same set of varieties, with the poor consuming lower quantities of the varieties. As in Li (2011), the gains in welfare from increased variety occur not because of heterogeneity in tastes in this setting but from being able to counteract diminishing returns to consuming increasing quantities of the same variety.

The model describes a spatial equilibrium where households are fixed in space, which captures a key feature of the Ethiopian context. Farmers in Ethiopia have only user rights to land, which they must relinquish if they migrate to town. Settlement patterns across Ethiopia have remained unchanged for decades and migration rates are amongst the lowest in sub-Saharan Africa, both of which are consistent with low urbanisation rates as well. And finally, it should be stressed that the loss of variety with remoteness in this setting pertains to rather basic goods in the consumption basket making a tradeoff with the intangible benefits of remoteness less plausible. More generally, this picture is consistent with Gollin et al (2017) who argue that there is little evidence that the higher consumption levels of urban areas are offset by lower non-monetary amenities in sub-Saharan Africa.
3 Data and Survey Design

Ethiopia offers a useful setting for examining the role of transport costs and other wedges in market development. It is landlocked which affects external trade while internal trade costs are strongly affected by its particular physical geography. It has a mean elevation of over 1000 metres and the bulk of the population lives on the high plateau, a terrain bisected by mountains. The terrain has also meant that Ethiopia has one of the lowest road densities in the world. While this potential bottleneck to market development has been recognised and resulted in substantial investment in new roads over the last decade\(^{13}\), it is still the case that vast swathes of rural Ethiopia are dependent on travel to market using mules on country tracks or on foot. Road density in Ethiopia has risen from 0.46 km per 1000 people to 0.57 km, which compares very poorly with the average in sub-Saharan Africa of 3.9 km/1000. With low urbanisation rates at 17 percent (compared to a sub-Saharan average of 33 percent) both physical and human geography in Ethiopia mean that remoteness from markets is fundamental to describing market access.

The data used here come from a purposeful survey of 295 villages in 100 districts across the four main regions of Ethiopia. The survey was designed to address two potential concerns in taking the theory to data. First, it was to ensure that the local market town was the only supplier of consumer goods and could thus serve as a benchmark for local availability. The villages were chosen such that they were linked directly only to one market town within the district. We also interviewed district officials and questioned them on the list of villages within districts and picked a subset of the remoter villages which had only one road or transport connection to the nearest market town. The aim was to ensure that the supply of goods to the village was only possible via the market town and hence the availability of goods in the market town would serve as the benchmark for the range available in the village albeit by separate roads. Each market town is linked to the village by a single road or track (and no other point of natural entry or exit); there are an average of three villages linked to the same market town. Figure 1 provides an illustrative map, based on two of the four sampled regions. Market towns are indicated in shades of blue, denoting differences in travel time to the farthest of the three villages they are connected to, while the black dots denote the villages. Table 2 examines our

\(^{13}\)The Ethiopian Government embarked on a major programme of investment in roads with a 10-year Road Sector Development Program in 1997 (RSDP 1997-2007). The first phase of the RSDP (1997-2002) focused on the rehabilitation of the main road network and since then has worked on an investment programme for new roads. See The Ethiopian Road Authority Manual (2015).
sampling frame: about 73% of villages within districts are connected to just one market town directly. Our sampling strategy thus produces villages that are not unusually situated given the hilly terrain. Secondly, by sampling three villages on average in the same district, and focusing on within district variation, we can account for placement at the level of the district. (We find no evidence of linear placement effects within districts as discussed below in Table 3). Accounting for the variation across districts allows us to concentrate on the relationship between local supply of variety in goods and local transportation costs, local (average) incomes and local heterogeneity in incomes. Data were collected in shops in the market towns closest to the villages and in shops and periodic markets (served by traders) in villages. Key village officials were interviewed about village characteristics, amenities and endowments. In addition, in each village, six households were interviewed, three chosen from the lower and three from the upper end of the wealth distribution, again with local consultation. The households were interviewed on their basic characteristics, consumption of consumer goods in terms of both variety and expenditures and their incomes (both from agriculture and outside agriculture if relevant).

We obtained data on the infrastructure, population, public goods, local incomes and production and most important, detailed data on transport infrastructure, travel times and quality of roads in each village. The data were collected both from district (woreda) officials and local village (kebele) representatives.

The main part of the survey involved the survey of shops in the nearest local market town on a full list of potential consumer goods across different categories of consumption from processed foods, household goods, toiletries to clothing and shoes\textsuperscript{14}. The next stage involved the collection of data on consumer goods available in the village. Depending on the village, there were small fixed local shops and periodic markets where traders bring consumer goods to the village\textsuperscript{15}. We surveyed both kinds of outlets on the variety (including brands) of goods and their prices, with additional questions on whether items from the list of goods available in the local market town were usually available even if they were not on sale on the day we visited them.

The key issue in the design of the survey as explained above was to ensure that the relationship between travel time and the availability of goods was not contaminated by the possibility that

\textsuperscript{14}A full list of items is available upon request.

\textsuperscript{15}In a series of articles, Skinner (1964) describes the role of periodic markets in rural China where itinerant traders bring goods to villages. This is a similar setting and as in China Rozelle et al. (2003), fixed stores co-exist with periodic markets.
roads (or improved roads) are more likely to be placed in villages that are also wealthier and more likely to attract a wider range of goods. The Ethiopian Road Authority supposedly uses five main criteria during the preliminary selection of new road projects which unsurprisingly target potentially more productive and populated regions. However, the targeting is effectively in two stages: the first, at the regional level and the second, within regions, at the district level - vitiating any concerns about targeting at the level of the village. Shiferaw et al. (2012) (p. 11) discuss these criteria and argue that while they suggest a degree of targeting to the district, it is not borne out in the data. They conclude that “Regressing our road infrastructure variables on district-level (or woreda) control variables, we find that most of the variation in road accessibility is captured by the year dummies and the region fixed effects.” Our data yield the same conclusion as Table 3 demonstrates. In this table, we examine the relationship between the type of village road, whether a surfaced road (tarmac or stone) or a dirt track and village-level variables that might capture placement, such as population density (measured by the number of households per km²), median income, the share of households in the village that receive support from the government’s safety net programme and the number of nearby hamlets that use the local periodic market, while controlling for district-level fixed effects. It is striking that for 151 villages, or half the sample, controlling for the district fixed effect completely explains the type of road in the village. Thus, over half the villages have their quality of road entirely unrelated to village-level variables, while for the remaining 134 villages, there is no evidence of a relationship between plausible village level variables (such as size and incomes) and the type of road. In the analysis that follows, we thus control for district fixed effects and base our identification of the relationship between variety available at the village level and travel time and local demand, entirely on the variation between villages within a

---

16 These are:
   i) Roads providing access to areas with economic development potential (20%)
   ii) Roads leading to areas with surplus food and cash crop production (20%)
   iii) Roads that link existing major roads (20%)
   iv) Roads providing access to large and isolated population centers (30%)
   v) Roads that bring balanced development amongst the regions in the country and that provide access to emerging regions (10%).

17 We present a basic set of covariates here, in line with the variables used later to examine the variety of goods available in villages relative to their nearest market town. Variations on this specification do not affect the conclusion that these variables do not explain the quality of village roads and thus there is little evidence that they are explicitly “placed” within villages.

18 Our measure of village median income is obtained from the interviews with the six households, three of which were deemed poor, while the other three were identified as rich by village officials. We also have measures of total grain and other production by village which proved far noisier.

19 A hamlet refers to a small number of households who do not live in the main village. A hamlet is connected to the village by a walking path or track. The only exit to the road to town is through the village. The average village has 7 hamlets in its neighbourhood.

20 The total sample size used is 285 because there was missing information on eleven villages for some village level variables needed to measure population density and village incomes.
We present two sets of descriptive statistics. Table 4 describes households’ perceptions of the effects of travel costs on consumer goods variety. We show this separately for households in the bottom and top of the village income distribution. The households were identified thus by village officials and it is useful to note that their incomes and assets tally with the description\footnote{We obtained data on monthly expenditures, agricultural and off-farm incomes and values of livestock. Uniformly, for poor households these values are at most a third of those of the rich households within villages. Note that the distribution of income across villages varies substantially.}. Poor and rich households differ sharply in their perceptions of the constraints posed by travel costs and distance. Just over half the poor but over 80% of rich households faced constraints in the set of manufactured goods available locally. Similar percentages said they would produce more for market and would travel more frequently if travel were easier. However, both groups were equally inclined to say that the rationale for travelling to town was to both sell produce and buy goods - even if the transactions of the rich are likely to be larger than the poor, as the first set of answers suggest.

What are the items that do not make the last mile into the village? Here there is consensus across households and this is reassuring because it describes a general lack of choice in particular item categories. Clearly, both rich and poor households face a lack of variety in similar item categories even if the rich are expected to spend more within them. The main sets of goods with items unavailable locally are clothing and linens followed by processed foods.

Table 5 describes the main characteristics of the villages in the survey. We begin with a discussion of the extensive margin of variety available: on average, villages have about half the items available in town and within these items, a third of all brands available in town. Seventy percent of towns are connected by a road made of tarmac or of stone to town (labelled a “good road”), while the remainder are served by a track or worse. The average distance to town is about 22 kilometres while the average time to travel to town by the most common form of transport is about an hour and 45 minutes. If the village hosts a periodic market, about 7 local hamlets are likely to participate; this is also our proxy for market size in the regressions below\footnote{The market size is at least 1 by construction since we count the main village as participating in the periodic market. Only 4% of villages have no surrounding hamlets. Alternative measures for market size include the population and village officials’ estimate of the average number of shoppers at the periodic market.}. The villages host about 65 households per square kilometre on average, which is higher than the Ethiopian average since it does not include pastoralist areas, but is about average for East Africa. We also use a proxy measure of whether the village is relatively...
poor compared to other villages in the sample by checking whether the village is covered by the Productive Safety Net Program (PSNP). This program is targeted to the poorer villages within poor districts\(^\text{23}\). If the village is part of the PSNP, we checked village records to discover how many households in the village receive such support. Forty-two percent of the sampled villages are in the government’s safety net: furthermore in half of these villages, over a third of households are covered by the programme. The share of households in each village who are in the PSNP is thus used as proxy for capturing the level of poverty in a village, which in turn allows us to compare relative poverty across villages. Finally, in terms of amenities in the village, most villages have a health centre and a primary school but access to pharmacies and secondary schools is low. About a quarter of the sample have reliable electricity (which means a reliable supply for 3 days a week or more) and 40% report a reliable cellphone connection in the same vein\(^\text{24}\).

### 4 Results

We now turn to the empirical analysis. We first investigate to what extent these factors such as transportation costs, market size and income distribution affect the distribution of variety across space. We then use data on prices both from our survey for small market towns and the villages and separately from the National Price Surveys that focus on the 118 larger market towns and urban centres across Ethiopia, to estimate the taste for variety captured by \(1 - \theta\). Finally, we use these estimates to examine the implications of remoteness on the welfare costs of falling variety. We describe these costs across space in our sample and also for the median urban consumer if faced by less variety, akin to being moved to a remote location.

To measure the extent of variety in manufactured consumer goods available we use a simple count of all items and brands available locally in village markets, across 10 different categories of items. Figure 2 presents a picture of the fall in availability of items across space, while Figure 3 displays the share of items (and brands) available relative to the nearest market town and demonstrates the decline in average shares as travel times to town increase. Clearly, travel time alone does not determine variety: we would expect that population and market size, median

\(^{23}\)Forty percent of the country’s 710 districts (\textit{woredas}) are covered by the PSNP and the programme supports about 8 million people or 10% of the population (IFPRI (2013)).

\(^{24}\)This may seem at odds with the reliability of the electricity connection; the mobile telephones are often deposited with a shopkeeper in town to be charged, or with the local shop if they have better access to electricity since households have poor access in general. The median access to electricity (and cellphones) is 0.
incomes and other village attributes might affect this as well. To understand these effects, we turn to our empirical specification.

We model the probability that a village $i$ with characteristics vector, $X_i$, (which includes transport times to the nearest market town, local market size, income distribution captured as a mean-preserving spread, and village-level amenities), has available exactly $Y_i$ items. We use a count data specification, with a generalised negative binomial (GNB) model below. The advantage of the GNB specification is that, in contrast to the Poisson, it allows for the variance to be different from the mean, thus accounting for the overdispersion\textsuperscript{25} in the data which is captured here through the introduction of regional fixed effects.

The main specification\textsuperscript{26} includes the time to travel to town using the most common form of transport\textsuperscript{27} and a measure of market size, proxied by the number of more remote hamlets that shop in the local sampled village\textsuperscript{28} or the periodic market located there.\textsuperscript{29} As an additional measure of market size we use (household) population density: the number of households per square kilometre. Finally, it is clear that some measure of local incomes is required. As explained above, we also surveyed six households in each village, where three households were drawn from the bottom of the distribution and the remainder from the top, as identified privately by local village officials. The households were interviewed on their average monthly consumption on manufactured goods, their income from both agriculture and other sources and their own assessment of their income, within three categories of rich, comfortable and poor. The measure of incomes and expenditures is noisy, given the light nature of the questionnaire and the usual difficulties of obtaining reliable estimates in one short interview. Instead of relying on any single measure, we construct a weighted average of all these measures, as a standardised normal variate, to proxy the distribution of income within villages. We use the bottom 20% and the top 20% (effectively, the income of the poorest and the richest households sampled), to capture the range of incomes or the mean-preserving spread, with the mean being standardised

\textsuperscript{25}We conducted tests for over dispersion, contrasting the Generalised Negative Binomial with the Poisson and the Negative Binomial distribution. The goodness-of-fit tests strongly reject the hypothesis of constant variances: Deviance goodness-of-fit $=1728$, with Prob $> \chi^2(201)= 0.00$ and the Pearson goodness-of-fit $= 1759.24$ with Prob $> \chi^2(201) = 0.00$. Introducing non-linearities does not affect the outcome and the Generalised Negative Binomial seemed the most appropriate alternative.

\textsuperscript{26}The number of items/brands available in the nearest market town is treated as the exposure variable, since the counts of availability are better understood as a fraction of the availability in town.

\textsuperscript{27}An alternative is to use the distance between village and town, together with controls for quality of road, by season. The results do not differ if these were included instead.

\textsuperscript{28}Rozelle et al. (2003) describe similar periodic markets in China.

\textsuperscript{29}An alternative measure is the community officials’ estimate of the average number of people who shop at the local periodic market. These are strongly correlated but the number of hamlets is the less noisy measure and thus preferred.
at zero\textsuperscript{30}. However, the distribution of incomes thus measured only captures variation within a village, and the proportions of poor and rich are likely to differ across villages. To anchor this income distribution, we use the share of households that receive support from the government’s Public Safety Net Programme, which is only targeted to villages deemed poor.

Table 6 presents the first set of estimates, using the total number of items available in the first 3 columns and then brands (across all item categories) in columns 4-6 as the dependent variable. Availability is strongly affected by travel times and the size of the local market. We report the coefficients in the table: the coefficients on the (ln) variables can be read as elasticities\textsuperscript{31}: a 1% increase in travel time, results in a fall of 0.07 - 0.09% in item varieties available locally. Thus, for an average village, a fall of an hour in travel time is associated with an increase of about 9 items or 18 brands on average. Market size matters too: we measure market size as the number of hamlets (comprising the village and any smaller clusters situated further down the track) using the local periodic market and so an extra hamlet added to the size of the local market (a 10% increase) would be associated with 12 extra items or 18 extra brands being available. Columns 2 and 3 (and 5-6) include measures of the measure of inequality (mean-preserving spread) and amenities (captured by reliable electricity and cellphone access). Inequality also plays a significant role here, and an increase in the spread from the median to the highest decile would raise availability by 3 items or 5 brands; while the introduction of reliable access to amenities raises availability by 7 items or 9 brands. Note that apart from transport costs and market size, we are describing an association here rather than causal effects. It is more useful to examine the impact on the coefficients of these key variables when controlling for amenities and it is reassuring that those effects remain similar in size and significance.

Figure 4 demonstrates the heterogeneity of the relationship between variety available across space and the types of items. Heavier, bulkier goods are more likely not to make the last mile: processed foods (which include bottled drinks here), clothing and footwear exhibit sharp declines within 30 minutes of travel time from the nearest market town. The results in Table 5 hide this heterogeneity and disaggregating this relationship by item groups suggests much sharper effects of remoteness for some groups compared to others.

\textsuperscript{30}We could also use estimates of village-level incomes as estimated by village officials. These were far noisier (even if correlated with the estimates obtained from the households), hence our reliance on the measures based on the survey of the households.

\textsuperscript{31}We use the ln(travel time) given the concave relationship between availability and travel time.
4.1 Prices, Markups and Remoteness

We now turn to examining the difference in prices between town and village. The data we gathered were meant to capture the extensive margin, i.e. whether a good is available in a market or not. As a result, the data have limitations in terms of its use for analysing the impact of distance on prices. First, given our focus on availability, we include a large number of generic brands - for instance, as long as a pair of jeans branded as “made in China” is available, and sold as different from another pair of jeans, it is treated as a different ”item”. However, this is a generic brand in that we cannot distinguish it as a specific brand like Levi’s or Gap. Second, even when the brands are clearly defined (for instance, as a particular brand of flour), the unit of measurement used at point of sale could vary across areas, making comparison between origin and destination difficult in terms of price. We deal with these difficulties in two ways. First, we examine the difference in prices between source town and village for branded items that can be compared in identical weight or volume units. We use 1380 observations on such matched price-brand pairs. This includes largely processed foods (sugar, pasta), beverages (bottled drinks and beer), ready-made clothing of particular brands, cosmetic and hygiene (soaps, detergents, toilet paper), household items (matches, batteries) and educational items (branded notebooks and pens). Second, we carried out a separate second survey of prices alone in half the sample (115 villages and 43 market towns) for specific item-brand pairs obtained from this survey to control for any measurement error in the first survey. This is also a more restricted set of items that does not include clothing or footwear. Note that restricting the matched item-brand pairs across villages in the first survey results in a smaller set of observations because in many cases units were missing or were different. We report the regression of prices paid in the village on prices paid in town and travel time in Table 7 using both sets of data. The regression examines the variation of prices across space for these matched pairs and also offers an estimate of the taste for variety, \( 1 - \theta \), as in Equation 6, which gives us two estimates, ranging from 0.09 to 0.13, which in turn give us estimates of a markup between 10.3% and 14.6%, where the markup is defined as \( 1 \theta \). In the next section, we use these estimates to construct the welfare costs of the loss of variety with remoteness. As we will see, these costs are very sensitive to the estimated taste for variety and the consequent estimates of elasticities.

The estimate of the taste for variety, \( \theta \), we obtain is similar whether we use the data on price differentials over relatively short distances, as in our surveys as reported above or between source town and 118 market towns, in the National Price Surveys collected by the Central
Statistical Authority. We use their data on prices of a set of 13 branded products collected monthly since 2010, where the 13 products are chosen such that we can map the source and destination prices accurately. We also obtain the travel time in minutes between the source and destination towns, using data from IFPRI, for 2010 and relying on the fact that until 2015, there was little new investment in these roads. The last column of Table 7 provides the estimate of the taste for variety using these data and this provides similar estimate as above, of a taste for variety of 0.12 and a markup of 14.4%.

The fact that we obtain similar estimates of the taste for variety over both remote locations and their small market towns, as well as the larger urban centres and their source towns (like the capital Addis Ababa), suggests that the taste for variety is similar across space. But the price wedge also depends on transport costs: the estimates in Table 7 suggest that the marginal transport cost (the estimate of $\beta$) is far lower between say, Addis Ababa and an urban centre than it is between a small market town and a remote village. The rapid investment in regional road infrastructure over the past twenty years has paid off for the urban consumer.

5 Welfare Costs of Remoteness

We now turn to examining the implications of the results obtained above for assessing the welfare costs to households of fading choice. We calculate the compensating variation required in terms of increased incomes to compensate for a loss in availability. We begin with the simplest account, using the basic model of identical consumers with a taste for variety.

In this simple model with Dixit-Stiglitz preferences, the utility function is as before:

$$u = \sum_{i=1}^{n} c_i^\theta$$  \hspace{1cm} (0 < \theta < 1.)  \hspace{1cm} (13)

When prices are the same for all goods this gives $c_i = y/(np)$ and equal expenditure shares: $s_i = pc_i/y = 1/n$. Substituting the expression for $c_i$ gives

$$u = \left(\frac{y}{p}\right)^\theta n^{1-\theta}.$$  \hspace{1cm} (14)

This implies that when $n$ changes from $n_0$ to $n_1$ income would have to change from $y_0$ to $y_1$ to
keep welfare unchanged where \( y_1 \) is given by

\[
\frac{y_0 - \theta}{p} n_0^{1-\theta} = \frac{y_1 - \theta}{p} n_1^{1-\theta}. \tag{15}
\]

The compensating variation \( CV \) is then given by \( y_0 + CV = y_1 \): to offset the welfare loss resulting from a reduction in the number of goods income \( y_0 \) would have to be increased (reduced) by the amount \( CV \) to keep welfare constant. In this case:

\[
\frac{y_1}{y_0} = \left[ \frac{n_1}{n_0} \right]^{\epsilon} \tag{16}
\]

where the elasticity is given by \( \epsilon = 1 - 1/\theta \).

For \( \hat{\theta} = 0.86^{32} \) this gives \( \epsilon = -0.15 \). Hence, for example, a 10% reduction in availability would require a 1.5% increase in income to keep welfare constant: \( CV = 0.015y_0 \).

In the case where we allow for inequality in incomes we characterise the welfare consequences below:

\[
u = \sum_{i=1}^{n} v_i \theta_i^\theta \quad (0 < \theta < 1; v_1 > v_2 > .. > v_n > 0). \tag{17}\]

This gives

\[
c_i = \frac{y_i}{p} \frac{v_i^{1/(1-\theta)}}{\sum v_i^{1/(1-\theta)}} \tag{18}\]

hence

\[
s_i = \frac{v_i^{1/(1-\theta)}}{\sum v_i^{1/(1-\theta)}} = a v_i^{1/(1-\theta)} \tag{19}\]

where \( a \) is a multiplicative constant. Hence the \( v \) parameters can be estimated (up to a multiplicative constant) from share data for the initial case \( y = y_0, n = n_0 \):

\[
v_i = \left[ \frac{s_i}{a} \right]^{1-\theta}. \tag{20}\]

As before, consider a reduction in availability \( (n_1 < n_0) \). (Since share data are observed only for the first \( n_0 \) goods, we cannot estimate the effect of an improvement in availability.) The

\[\text{This is the estimate from the first, variety survey, see Table 6.}\]
expression which defines $y_1$ is:

$$y_1 = \sum_{i=1}^{n_1} s_i^r.$$  \hspace{1cm} (21)

(It may be verified that this reduces to (3) in the Dixit-Stiglitz case.)

In order to calculate the compensating variation of a loss of variety in consumer goods, we examine what fraction of consumption expenditures on manufactured consumer goods falls as items fall out of the consumer basket. We rank the items in order of their budget share in the basket of the median urban consumer: the thought experiment involved in constructing welfare costs and the CV is to calibrate the loss of the items with the lowest share or in terms of the framework above, the llast few goods to enter a remooter market.

In order to construct these estimates, we require budget shares for spending on manufactured goods. We use data from the Household Consumption Expenditure Survey (HICES) 2015-16 which provides the budget shares for both rural and urban households for 95 manufactured consumer goods. We consider the loss to the median urban consumer of losing the last set of varieties in the current basket – and calibrating this loss in consuming these varieties based on both the estimated taste for variety and the budget shares. The average welfare cost of losing varieties using budget shares derived from urban household surveys for the median decile is estimated at an average of 5%- 7% (using the two estimates of mark-up in prices of 10% and 14.6%) of consumer expenditures on manufactures. Note that the top 20% of items take up more than half of spending on all manufactured items which implies that the compensating variation from the loss of marginal items is small - or reflecting the decline in marginal utility of new or additional items. These top 20% of items include processed foods (edible oil, beer and flour but also medicines and detergents). The quantile plots of cumulative budget shares and the compensating variation (CV) in Figure 5 describes the distribution and demonstrates that the sharpest falls in welfare occur for the top fraction of available items. We also examine the welfare loss over distance for the "average" village, using the number of items available in villages and the budget shares from the HICES to describe the compensating variation, keeping all other attributes of villages at their average. Figure 6 describes the loss in welfare across space, again using the two estimates from Table 6. As is clear, the two different estimates of $\theta$ and thus the mark-up generate very different effects of welfare losses.
6 Conclusion

We have described a model where consumers are affected by transport costs, not only through changes in prices, but also through changes in the set of available goods. In this model a reduction in transport costs increases consumer welfare in three ways. First, it increases the value of income from sale of crops. Secondly, it lowers the price of consumer goods. Finally, it increases the number of varieties available at a given distance from a market town. We have extended this framework to take account of heterogeneity in the size of markets and in the distribution of income. This model was tested using data collected in a purpose-designed survey of villages in Ethiopia, each served by a single larger market at the district level. We find that variety declines sharply with transport costs. It is also strongly affected by the size of the local market and the distribution of income.

While the new economic geography has led to a large number of empirical studies on the effect of international trade on variety, there is comparatively little empirical work on the effect of domestic trade on the number of varieties available to consumers and only so for developed countries. This is likely to be a much more important issue in developing countries where transport costs are very much higher. This is one of the few papers that addresses the loss in variety in consumption with remoteness: consumer choice fades away with distance in developing countries. The magnitude of the effects we found in Ethiopia suggests that when comparing incomes across space within countries it is not sufficient to correct for price differentials, keeping the basket of goods fixed. That ignores the availability effect which according to our results dramatically affects the options open to consumers in distant locations. Distance reduces welfare not only by inducing a deterioration of the terms of trade of a village trading with a market town but also reduces the number of goods that will be available to consumers in the village. The size of the welfare effects we find depend both on domestic trade costs within countries and the spending on consumer goods - for instance, the Nigerian case (see Atkin and Donaldson (2015) ) where both intra-trade costs and consumer spending are far higher offers a sharp contrast to Ethiopia. We describe a spatial equilibrium where variety falls across space despite households demonstrating a similar taste for variety in goods but households are fixed in space: given the restrictions on land ownership and the difficulties of migration in Ethiopia, this seems consonant with the context.

What do these results tell us? First, they demonstrate that there are significant welfare losses
to low variety in manufactures and that intra-trade costs (both mark-ups and transport costs) matter in affecting this margin. Second, the average costs to consumers of about 5%-7% of consumer expenditures on manufactures while not small, reflects the fact that Ethiopian consumers are poor and their share of spending on manufactures is low. These costs will increase with rising incomes unless domestic trade costs fall as well.

We have shown how variety in manufactures fades with distance and associated transport costs. Reductions in transport costs increase consumer welfare through higher incomes, lower prices - and increased variety. This also has implications for welfare measurement: poverty is underestimated since people in remote places have little to choose – but equally, when changes such as infrastructure investments raise availability, rates of decline in poverty will be underestimated too.

Number of households 906 908

Notes: The data here come from the survey of six households in each village, chosen so that three were deemed to be representative of poor households in the villages and the other three deemed relatively rich. This was in consultation with village-level officials.

Notes: Market size is measured as the number of nearby hamlets (including the main village sampled) that use the periodic market and fixed shops in the village. The share of poor households is obtained from the number of households in the village who are part of the PSNP programme targeted at poor villages, while income spread measures the difference in incomes between the richest and poorest households in the sample, with the mean standardised to zero, a mean-preserving spread.
Notes: The graph displays lowess graphs of shares of items available in the village relative to the associated market town, disaggregated by item group to examine heterogeneity in the fall in variety over travel time. Heavier, bulkier items such as processed food and drink and hardware display a sharper fall in availability by travel time.
Table 7 Prices between source town \((P)\) and destination \((P_j)\)

\[
P_j = \frac{P}{\theta} + \frac{\beta S_j}{\theta}
\]

Notes: Column (2) uses the prices of branded items in village and associated towns in identical weight or volume units from the availability survey with data from 187 villages and 77 market towns. Column (3) uses similar prices on branded items from a follow-up survey on prices alone in 115 villages and 43 market towns as a consistency check. Column (4) uses data (on 13 items whose source town is established) from the National Price Survey conducted by the Central Statistical Authority in 118 market towns from 2010-2016. We use these years since the road quality (and thus travel time) between source town and market town can be assumed to be unchanged. Note that this last set of prices reflects national differences rather than within-district variation in as in Columns 2 and 3.
Figure 5 Quantiles: Cumulative Budget Shares and Compensating Variation

Notes: The graph above is a quantile plot of cumulative budget shares and the compensating variation (CV) or welfare cost of losing varieties for the median household in town. This is estimated using the budget shares for an urban household from the Household Consumption Expenditure Survey (HICES) 2015-16 for 95 manufactured consumer goods.
Figure 6 Welfare Costs of Remoteness for Average Village: Compensating Variation by Travel Time in Minutes

Notes: The graphs above describe the compensating variation or welfare loss by remoteness from town, using the average number of items available by travel time and the associated budget shares from HICES as in Figure 5 and fixing all other village characteristics at the average. The graphs demonstrate the difference in CV associated with the range of estimates of between 10% and 15%.
